Conjugated Systems, Orbital Symmetry and UV Spectroscopy

Introduction
There are several possible arrangements for a molecule which contains two double bonds (diene):

**Isolated**: (two or more single bonds between them)

\[ \text{CH}_2 = \text{CH}-\text{CH} = \text{CH}-\text{CH}_2 \]

**Conjugated**: (one single bond between them)

\[ \text{CH} = \text{CH}-\text{CH} = \text{CH}_2 \]

**Cumulated**: (zero single bonds between them: allenes)

\[ \text{C} = \text{C} = \text{C} \]

**Conjugated** double bonds are found to be the most stable.
Stabilities
Recall that heat of hydrogenation data showed us that di-substituted double bonds are more stable than mono-substituted double bonds.

\[
\text{H}_2, \text{Pt} \quad \Delta H^\circ = -30.0\text{kcal}
\]

\[
\text{H}_2, \text{Pt} \quad \Delta H^\circ = -27.4\text{kcal}
\]

When a molecule has two isolated double bonds, the heat of hydrogenation is essentially equal to the sum of the values for the individual double bonds.

\[
\text{H}_2, \text{Pt} \quad \Delta H^\circ = -60.2\text{kcal}
\]

For conjugated dienes, the heat of hydrogenation is less than the sum of the individual double bonds.

\[
\text{H}_2, \text{Pt} \quad \Delta H^\circ = -53.7\text{kcal}
\]

The conjugated diene is more stable by about 3.7kcal/mol. 
(Predicted \(-30 + (-27.4) = -57.4\text{kcal}\), observed \(-53.7\text{kcal}\)).
Allenes, which have **cumulated** double bonds are less stable than isolated double bonds.

\[
\text{H}_2, \text{Pt} \quad \Delta H^o = -69.8 \text{kcal}
\]

Increasing Stability Order (least to most stable):
- Cumulated diene: -69.8 kcal
- Terminal alkyne: -69.5 kcal
- Internal alkyne: -65.8 kcal
- Isolated diene: -57.4 kcal
- Conjugated diene: -53.7 kcal
Molecular Orbital (M.O.) Picture

The extra stability of conjugated double bonds versus the analogous isolated double bond compound is termed the **resonance energy**.

Consider buta-1,3-diene:

\[
\begin{align*}
\text{H}_2, \text{Pt} & \quad \rightarrow & \quad \text{H}_2, \text{Pt} \\
\text{C} &= \text{C} & \Delta H^0 = -30.1 \text{kcal} \\
\text{C} &= \text{C} & \Delta H^0 = -56.6 \text{kcal}
\end{align*}
\]

(2 x –30.1 = –60.2 kcal). Resonance energy of buta-1,3-diene is 3.6 kcal.

The C2-C3 bond is much shorter than a normal alkane single bond (1.48 Å vs. 1.54 Å). This is mainly due to the \( \pi \) bonding overlap (resulting in some double bond character).

The planar arrangement, and the alignment of the p orbitals allows overlap between the two double bonds. The electrons are **delocalized** over the full length of the molecule.

This delocalization of electrons creates partial double bond character between C2 and C3.

Lewis structures cannot **accurately** depict delocalized structures, and we turn to molecular orbital theory.
Let us recap simple MO theory using ethene:

Each p orbital has two lobes, with differing wavefunction sign (+/-, black/white, shaded/unshaded; NOT electrical charges).

A $\pi$ **bonding** orbital is formed by overlap of p lobes with the **same** wavefunction sign. (*Constructive overlap*).

A $\pi$ **anti-bonding** orbital is formed by overlap of p lobes with **opposite** wavefunction sign. (*Destructive overlap*).

Electrons have a **lower** potential energy in the bonding MO than in the original p orbitals, and a **higher** potential energy in the anti-bonding orbitals.

In the ground state of ethene, two electrons fill the bonding MO, and the antibonding MO is empty.
MO Rules:

Constructive overlap = bonding
Destructive overlap = antibonding
Number of $\pi$ MO’s = Number of p orbitals
The MO energies are symmetrically distributed above and below the initial energies of the p orbitals.
Half the MO’s are bonding, the other half antibonding.

So, now for buta-1,3-diene:

There are 4 p orbitals to consider.

The lowest energy MO will have the greatest number of favorable interactions (i.e. with all the p lobes interacting constructively).

This is called $\pi_1$.

(Although buta-1,3-diene is not linear, it is easier and convenient to represent it as such).

This MO places electron density on all four carbon atoms.

There are 3 bonding interactions and this MO delocalizes the electrons over four nuclei.

This explains why there is partial double bond character between C2 and C3.
The next MO has a node in the center of the molecule.

This is a classic diene MO, with bonding between C1-C2, and C3-C4.

There is an antibonding interaction between C2-C3.

This MO has two bonding and one antibonding interactions – so we expect it to be overall bonding, but higher in energy than \( \pi_1 \).

The third MO has two nodes.

With two antibonding and one bonding interaction, overall this is an antibonding MO, and is denoted by an asterix (*)

The fourth MO has 3 nodes, and is completely antibonding.

This is the highest energy MO.
Buta-1,3-diene has 4 π electrons to accommodate, and each MO can hold two electrons, with the lower energy MO’s being filled first.

Both bonding MO’s are filled, and the antibonding MO’s are vacant.

Generally (and unsurprisingly!) stable molecules tend to have filled bonding MO’s and vacant antibonding MO’s.

The planar conformation of buta-1,3-diene is the most stable conformation since it allows the overlap of the 4 p orbitals.

There are two planar conformations that buta-1,3-diene can adopt. (s-trans and s-cis conformations).

They are single bond analogues of cis/trans isomers.
The $s$-trans (single-trans) conformation is about 2.3 kcal lower in energy than the $s$-cis conformation, which arises from the steric repulsions of the hydrogens.

The barrier to rotation for these conformers is 4.9 kcal.

This low energy difference means at room temperature these conformations are easily and rapidly interconverting.

**Allylic Cations**
Allylic cations are stabilized by resonance with the adjacent double bond, which delocalizes the positive charge over two carbon atoms.

\[
\text{Br} \quad \text{-Br}^{-} \quad = \quad \frac{1}{2}^+ \quad \frac{1}{2}^+ \\
\text{Br} \quad \text{Br}
\]

The delocalized cation can be represented by the two resonance structures, or the combined structure.

**1,2- and 1,4-Additions**
Allylic cations are often intermediates when there is electrophilic addition to conjugated dienes.

Consider the case of electrophilic H-Br addition to buta-1,3-diene:

1,2-Addition and 1,4-addition refer to the relationship of the carbon atoms to which the H and Br are added.
Mechanism for 1,2- and 1,4-Addition of HBr
The mechanism is the same as for any electrophilic addition (protonation gives a cation, nucleophile attacks the carbocation) except now the cation is allylic.

The allylic cation is resonance stabilized and the positive charge is spread over two carbon atoms.

The nucleophile (bromide ion) can now attack either of the positively charged carbons, generating the mixture of products.

So which is the major product...?
Kinetic and Thermodynamic Control

The addition of HBr to buta-1,3-diene is temperature dependent (i.e. the ratio of the products is greatly affected by variations in temperature).

At the lower temperature, the 1,2-addition product dominates, whereas at the higher temperature the 1,4-addition product is major.

The more stable product would be predicted to be the 1,4-addition product since it has an internal double bond.

Notice that at lower temperatures the more stable product is not the major product formed.
At −80°C
The T.S. for 1,2-addition has a lower activation energy because it generates a more stable carbocation (2° versus 1°).
The 1,2-addition will therefore always occur faster than the 1,4-addition.

The attack by bromide ion on the cation is highly exothermic, and therefore once the product has formed it is unlikely to undergo the reverse ionization reaction at this temperature.

Therefore at this temperature, the product that is formed more quickly is the product that dominates – this is called Kinetic Control.

(The 1,2-addition product is called the kinetic product).
At 40°C
At this higher temperature there is now sufficient energy for reverse reactions to proceed.

Notice that the activation energy required for the reverse reaction of the 1,2-product is less than for the 1,4-product. This means it is easier for the 1,2-product to undergo the reverse reaction (i.e. regenerate the allylic cation).

Although the 1,2-product is still formed faster, it also returns to the allylic cation faster than the 1,4-product. An equilibrium is set up, and now the relative stabilities of the two products determines their concentrations (product ratio).

The 1,4-product is the more stable product, and at this temperature it is the major product.

Since the thermodynamics now control the reaction, this reaction is said to be under Thermodynamic Control.

(And the product is the thermodynamic product).

In general, if a reaction is non-reversible, the kinetic product dominates.
If the reaction is reversible, then the thermodynamic product dominates.
Allylic Radicals
In an analogous fashion, allylic radicals are also resonance stabilized.

Recall that under free radical conditions, low concentrations of bromine will react with alkenes via substitution (as opposed to the classical addition processes).

This is a free radical process. The light initiates the reaction by dissociating a bromine molecule into two Br radicals.

The Br• abstracts a hydrogen selectively from the allylic position, thus generating an allylic radical which is resonance stabilized.
The allylic radical then abstracts a bromine atom from a bromine molecule to generate the allylic bromide product.

\[
\begin{align*}
\text{CH}_3\text{CH}_2\text{-H} & \rightarrow \text{CH}_3\text{CH}_2\bullet + \text{H} \bullet & \Delta H = +98 \text{kcal} \\
(\text{CH}_3)_2\text{CH-H} & \rightarrow (\text{CH}_3)_2\text{CH} \bullet + \text{H} \bullet & \Delta H = +94 \text{kcal} \\
(\text{CH}_3)_3\text{C-H} & \rightarrow (\text{CH}_3)_3\text{C} \bullet + \text{H} \bullet & \Delta H = +91 \text{kcal} \\
\text{CH}_2=\text{CHCH}_2\text{-H} & \rightarrow \text{CH}_2=\text{CHCH}_2\bullet + \text{H} \bullet & \Delta H = +88 \text{kcal}
\end{align*}
\]

The allylic radical has the free electron delocalized over two carbons, and the bromine may become attached to either carbon.

Unsymmetrical substrates can give rise to mixtures of products which result from allylic resonance structures. E.g.

The Br• which is generated then continues the chain.

The allylic hydrogen is selectively removed since it has the lower BDE:

Unsymmetrical substrates can give rise to mixtures of products which result from allylic resonance structures. E.g.
Molecular Orbitals of Allylic Systems

All three p orbitals must be aligned **parallel** so they can overlap.

There is partial π bonding between C1-C2 and C2-C3, and the radical is delocalized on the **end** two carbons.

The three overlapping p orbitals interact to form 3 MO’s.

antibonding  \( \pi_3^* \)  
nonbonding  \( \pi_2 \)  
bonding  \( \pi_1 \)

The **lowest** energy MO has all **bonding** interactions and the **highest** energy MO has all **antibonding** interactions.

Since MO’s are symmetrically displaced about the energy of the isolated p orbital, **for odd numbers** of MO’s, one MO must lie in the **middle** of the energy levels.

This is called the **Non-Bonding** MO, \( \pi_2 \).

\( \pi_2 \) must contain one node, and so it has the (unusual) structure with a node at C2. This MO is non-bonding.

**Note** that the single electron (radical) is in \( \pi_2 \) which has density on C1 and C3 only.
Other Allyl Systems
The allyl cation, anion and radical all have the same MO structures, but differ in the **number of electrons** contained within them.

The allyl cation has no electrons in the $\pi_2$ MO, whereas the allyl anion has two electrons in the $\pi_2$ MO.

This MO description explains why the allylic anion and cation have partial charges on carbons C1 and C3.
**S\textsubscript{N}2 Displacements from Allylic Halides**

Allylic halides and tosylates demonstrate enhanced reactivities in reactions with nucleophiles.

The rate is enhanced because the T.S. is lowered in energy through delocalization of electrons.

The T.S. for these S\textsubscript{N}2 reactions resemble the allylic arrangement because of the perpendicular p orbital. This allows a delocalization of the electrons in the T.S. and so lowering the energy of the system, and therefore lowering the activation energy and thus enhancing the rate.
The Diels-Alder Reaction
This is one of the most powerful reactions in organic chemistry, and is especially useful for creating 6 membered rings.

The Diels-Alder reaction is also called a [4+2] cycloaddition, because it involves $4\pi$ electrons from one molecule and $2\pi$ electrons from another.

The molecule that reacts with the diene component is called the dienophile, and is usually electron deficient (alkene or alkyne bearing electron withdrawing groups).

The diene molecule is usually electron rich, and electron donating groups enhance the reactivity of dienes in cycloadditions.

Two $\sigma$ bonds are created at the cost of two $\pi$ bonds (thus energetically favorable).
E.g.

\[
\text{diene} \quad \text{dienophile} \quad \text{Diels–Alder adduct}
\]

\[
\begin{align*}
\text{H}_3\text{C}-\text{C} & \quad \text{N}=\text{C}-\text{C} \quad \text{H} \\
\text{H}_3\text{C} & \quad \text{C} \quad \text{H} \quad \text{H} \\
\end{align*}
\]

\[
\begin{align*}
\text{O} & \quad \text{C} \quad \text{OCH}_3 \\
\text{C} & \quad \text{OCH}_3 \\
\end{align*}
\]

\[
\begin{align*}
\text{CH}_3\text{O} & \quad \text{CH}_3\text{O} \\
\text{O} & \quad \text{O} \\
\text{C} \quad \text{C} \quad \text{O} & \quad \text{O} \\
\end{align*}
\]

Mechanism
The mechanism of a Diels-Alder is a *simultaneous* cyclic movement of *six electrons*.

The reaction is *concerted*, with bonds breaking and forming at the same time.

The geometry required for the *concerted* process must allow the p orbitals at the ends of the diene to overlap with the p orbitals of the dienophile.

---

**Stereochemistry of the T.S.**
There are **three** main rules for Diels Alder reactions:

1. *s-cis* conformation of the diene is required.
2. Syn addition (*stereochemistry is maintained*).
3. Endo rule.
s-cis conformation
The diene must be in an s-cis conformation to react as a diene in a Diels Alder reaction.

![Diagram showing s-cis and s-trans conformations](image)

This is so that the end p orbitals can still overlap with those on the dienophile.

Even though the s-trans is more stable than the s-cis conformation, the energy difference is low, and at reaction temperatures the equilibrium is fast enough for Diels alder reactions to proceed.

![Molecules with varying reactivity](image)

As expected, molecules with groups that disfavor the s-cis conformation will react slower, and dienes unable to attain the s-cis conformation will not undergo Diels Alder reactions.

Cyclopentadiene, which has the diene fixed in the s-cis formation, is a very reactive diene for DA reactions.
Syn Stereochemistry (stereochemistry is maintained)
The dienophile adds to one face of the diene, and the *concerted* reaction mechanism does not allow for any substituents to change their stereochemistry.

E.g.

\[
\begin{array}{c}
\text{cis} + \text{cis (meso)} \\
\text{trans} + \text{trans (racemic)}
\end{array}
\]

\[
\begin{array}{c}
\text{cis (meso)} \\
\text{trans (racemic)}
\end{array}
\]
The Endo Rule
Substituents can end up either in the exo or endo positions.

Normally the largest substituent goes into the exo position, because that is the sterically least demanding position.

However, there is a more dominant effect: when a dienophile has a $\pi$ bond as a substituent on the dienophilic multiple bond, there is secondary orbital overlap, which results in endo addition.

(Notice that almost all dienophiles have these type of substituents: E.g. –CN, -CO$_2$CH$_3$, etc.)
This is because the p orbitals in the electron withdrawing group interact with the p orbitals on the central C2 and C3 of the diene.

This secondary overlap lowers the energy of the TS and so is favored.
Pericyclic Reactions

Pericyclic reactions involve concerted bond breaking and formation within a *closed ring of interacting orbitals*.

The Diels alder cycloaddition is a **pericyclic reaction**. The TS of the DA shows each carbon atom of the new ring contributing one orbital to the closed loop of orbitals.

A concerted pericyclic reaction has a single transition state, and the activation energy must be supplied either by heat (thermal initiation) or UV light (photochemical initiation).

Many pericyclic reactions proceed only by one type of initiation.

Often if both types of initiation work, they give *different* products.
Woodward Hoffman Rules
Pericyclic reactions were not well understood until in 1965 the Woodward Hoffman rules of conservation of orbital symmetry were developed.

Consider the DA of butadiene and ethene:

Butadiene has 4 MO’s, and ethene has two MO’s.

The movement of electrons (i.e. reaction) involves the highest occupied molecular orbital (HOMO) of one molecule and the lowest unoccupied molecular orbital (LUMO) of another.

In a DA, the diene acts as the electron rich ‘nucleophile’ and the dienophile is the electrophilic counterpart.

The HOMO of the diene interacts with the LUMO of the dienophile.

The electrons that move are from the HOMO since they are the least tightly bound.
It is the arrangement of the orbitals in the HOMO (HOMO symmetry) that determines the course of the reaction.
The electrons are transferred into the LUMO of the electrophile – this is the $\pi^*$ MO of ethene.

A concerted reaction may only take place if the electrons can flow smoothly from the HOMO to the LUMO.

This can only occur if the orbitals have the correct symmetry – this means the orbitals must interfere constructively (same wave sign with same wave sign).

The bonding interactions lower the TS energy and promote the concerted reaction.

The matching of the orbital signs means this reaction is **Symmetry Allowed**.
Forbidden Cycloadditions
If the interaction between orbitals had been deconstructive, the reaction would be said to be symmetry forbidden.

The cycloaddition between two molecules of ethene to generate cyclobutane is a symmetry forbidden reaction.

\[
\begin{array}{c}
\text{H}_2\text{C}=\text{C} \quad \text{H}_2\text{C}=\text{C} \\
\end{array}
\]

This [2+2] cycloaddition requires the HOMO of one ethene to interact with the LUMO of the other.

\[
\begin{array}{c}
\text{H}_2\text{C}=\text{C} \quad \text{LUMO} \quad \text{H}_2\text{C}=\text{C} \\
\text{H}_2\text{C}=\text{C} \quad \text{H}_2\text{C}=\text{C} \\
\end{array}
\]

This causes antibonding interactions, orbital symmetry is not conserved – it is symmetry forbidden.

Thus, heating ethene does not generate cyclobutane.
Photochemical Cycloadditions
In general, thermally disallowed cycloadditions can be made to occur under photochemical initiation.

\[ \text{Photochemical initiation occurs when a photon of correct energy hits ethene, and a } \pi \text{ electron is excited to the next highest energy level.} \]

\[ \text{The DA reaction now involves the LUMO of one ethene and the HOMO (now } \pi^* \text{ of the excited ethene, HOMO*) of the other.} \]
This time the interaction is all **constructive**.

The [2+2] DA is **thermally** forbidden but **photochemically** allowed.

In general, thermally allowed reactions are photochemically forbidden, and vice versa.

**UV Absorption Spectroscopy**

Ultraviolet (UV) spectroscopy measures electronic transitions, and gives useful information concerning double bonds and especially conjugation effects.

Sigma bonds in general do not become excited under irradiation, but π bonds have electrons that are easily excited into higher energy levels.

The difference in energy between the levels determines the wavelength of light absorbed.
Consider the excitation of ethene:

![Diagram of ethene ground state and excited state](image)

The $\pi \rightarrow \pi^*$ transition requires 164 kcal (686 kJ/mol), which corresponds to a wavelength of 171 nm.

The wavelength of maximum absorbance is called $\lambda_{\text{max}}$. (Recall that wavelength is inversely proportional to energy, so longer wavelength is lower energy).
A plot of absorbance versus wavelength (nm) for a conjugated system. The peak absorbance, $\lambda_{\text{max}}$, is at 222 nm. The molecule represented is $CH_2=CH-C=CH_2$ with a methyl group ($CH_3$) on one of the carbon atoms. The solvent used is methanol.
(At least) two factors can alter values of $\lambda_{\text{max}}$.

**Conjugation** lowers the energy differences between energy levels, and so conjugated dienes absorb at longer wavelengths than isolated dienes, and trienes absorb at longer wavelengths than dienes, etc.

E.g.

\[
\begin{align*}
\text{CH}_2=\text{CH}- & \quad \text{CH}_2=\text{CH}-\text{CH} & \quad \text{CH}_2=\text{CH}-\text{CH}-\text{CH} & \quad \text{CH}_2=\text{CH}-\text{CH}-\text{CH}-\text{CH}
\end{align*}
\]

$\lambda_{\text{max}} = 176\text{nm}$  $\lambda_{\text{max}} = 180\text{nm}$  $\lambda_{\text{max}} = 223\text{nm}$  $\lambda_{\text{max}} = 258\text{nm}$

Alkyl group substitution on double bonds also causes absorption to occur at longer wavelengths.

E.g.

\[
\begin{align*}
\text{CH}_2=\text{CH}- & \quad \text{CH}_2=\text{CH}-\text{CH} & \quad \text{CH}_2=\text{CH}-\text{CH}-\text{CH}
\end{align*}
\]

$\lambda_{\text{max}} = 217\text{nm}$  $\lambda_{\text{max}} = 232\text{nm}$
